This study is part of the research program 'Reforming Social Security'. Financial support of Foundation Instituut GAK is gratefully acknowledged. Chen is funded by the Chinese Scholarship Council. We thank Janet Gornick (Director of the Luxembourg Income Study) for permission to post Leiden LIS Budget Incidence Fiscal Redistribution Dataset at our website (www.hsz.leidenuniv.nl). This dataset presents the disentanglement of income inequality and the redistributive effect of social transfers and taxes in 36 LIS countries for the period 1970-2006 (Waves I - Wave VI of LIS). We thank Palvolgyi Balazs, Jim Been, When-Hao Chen, Marike Knoef, Arnaldur Sólvi Kristjánsson, Susan Kuivalainen, Judith Niehues, and Olaf van Vliet for useful suggestions and for comments on a earlier draft and presentations of this paper. The usual disclaimer applies.
Both this Working Paper and our dataset will become available at the LIS website as well.

Abstract

The aim of this paper is to offer detailed information of fiscal redistribution in 36 countries, employing data that have been computed from the Luxembourg Income Study's micro-level database. LIS data are detailed enough to allow us to measure both overall redistribution, and the partial effects of redistribution by several taxes or transfers. We elaborate on the work of Jesuit and Mahler (2004) and Mahler and Jesuit (2006), and we refine, update and extend their Fiscal Redistribution approach. LIS data allow us to decompose the trajectory of the Gini coefficient from primary to disposable income inequality in several parts: we will distinguish 11 different benefits and several income taxes and social contributions in our empirical investigation across countries.

First, we use LIS data to analyze income inequality and the redistributive effect of social transfers across countries in a descriptive way. Then we proceed with a simulation approach for 36 countries for which we decompose income inequality through several taxes and transfers. We analyze the redistributive effect of several social programs, like unemployment benefits or pensions and income taxes. We develop a budget incidence simulation model to investigate to what extent several social transfers contribute to the overall redistribution in modern welfare states under a strong assumption that the absence of social transfers and taxes would not change individual behavior and labor supply.

Among all countries listed in this paper, Denmark and Sweden have the smallest income disparity, while Peru and Colombia have the largest. Nordic countries show the most equally distributed disposable incomes and primary incomes, comparing to the countries in other types of welfare states. On average, large primary income disparity exists in Anglo-Saxon countries. Generally speaking, European countries achieve lower levels of income inequality than other countries.

With respect to the redistributive effect, our budget incidence analysis indicates that the pattern is diverse across countries. The largest redistribution is found for Belgium, while Colombia and Peru show rather limited overall redistributive effects. On average, transfers reduce income inequality by over 85 percent, while taxes account for only 15 percent of total redistribution. Among all welfare states, Continental European countries (Belgium, France, Germany, and Luxembourg) achieve the highest level of the reduction of initial income inequality.

As far as social programs is concerned, in most countries two dominant income components account for above 50 percent of total reduction in income inequality: the public old age pensions and the survivors scheme, and the income taxes. For example, in Southern European Countries the public old age benefits account for over 80 percent of total redistribution, while these figures are much lower for Anglo-Saxon Countries (20-34%), for Nordic Countries (31-48%), for Continental European Countries (47-57%), and for Central Eastern European Countries (54-70%). In Anglo-Saxon Countries income taxes play a major role (above 30%) compare to other countries (with the exception the United Kingdom). Also the redistributive effect of social assistance and child and family benefits in the Anglo-Saxon Countries are relatively high in a comparative setting (9-28%). In Nordic Countries also a variety of other social programs contribute to the reduction of inequality, especially the disability scheme (9-15%). Remarkably, across countries all other social benefit programs seem to have rather limited redistributive effects, although the unemployment compensation benefits do have some effect too.

Key words: welfare states, social income transfers, inequality, Gini coefficient, LIS
JEL-codes: H53, H55, and I32

1. Introduction

The growing interest in national and cross-national differences in earnings and income inequality has produced a wide range of studies (see Gottschalk et al, 1997; Brandolini and Smeeding, 2007; OECD, 2008; and Lambert et al, 2010). For many countries, studies are showing how income inequality has changed during recent years. An important development has been the launching of the Luxembourg Income Study (LIS) in which microdatasets from various countries have been "harmonised". Consequently it is possible to study income inequality across countries (see Atkinson et al, 1995). However, the improvement in methods of measurement and in empirical knowledge is in contrast with the lack of insight into causes of changes in equality over time.¹ This should perhaps not come as a surprise as the distribution of income in a country is the outcome of numerous decisions made over time by households, firms, organizations and the public sector. One could think of an almost infinite number of micro-level causes for differences and changes in income inequality (Gottschalk and Smeeding, 2000).

In this paper, we focus on the effect of taxes and transfers in redistributing income. Our expectation is that social transfers are mainly directed to lower income groups, while income taxes are mainly paid by the rich, and therefore both will have an impact on income (re)distribution. We use the traditional budget incidence approach—despite some methodological problems we will address—to study the combined effects of all taxes and transfers on the income (re)distribution. The distribution of primary or wage and salary income is compared with the distribution of income after tax and after social transfers.

We present empirical results by analysing absolute *levels* of income inequality across countries for the most recent data year available (around 2004). Many factors make it difficult to compare the redistributive effect of taxes and transfers across countries (differences in income concepts, the income units, (summary) measures, equivalence adjustments and other factors). Moreover, there are numerous possible ways to analyse the impact of taxes and transfers on the distribution of income; some of these approaches are listed in our references.² It is generally agreed upon that there is no single 'correct' methodology. However, the budget incidence approach is - still - a standard methodology for studying the combined effects of all taxes and transfers on the magnitude of (re)distributing income.

The increasing income inequality observed for most—but not all—Western economies over the last decades has coincided with many structural changes in the economic system. For many countries the main forces behind growing disposable income inequality are the growth of inequality of earned market income, demographic changes, changes in household size and composition, and other endogenous factors. Atkinson (2000:17) concludes that we should not expect the same development in all countries, because the distribution of income is subject to a wide variety of forces (which may differ over countries). The evolution of income inequality is not simply the product of common economic forces: it also represents the impact of institutions and national policies. We focus on the redistributive effect of taxes and transfers to that end.

1 OECD (2008) summarizes trends and driving factors in income distribution and poverty on the basis of a harmonized questionnaire of OECD Member Countries (i.e., distribution indicators derived from national micro-economic data).

2 Among others, see Atkinson et al (2000), Gustafson and Johanson (1997), Lambert et (2010), Moene and Wallerstein (2003), Swabish et al (2006).

Our contribution to the literature is threefold.

First, we provide evidence on the redistributive effect of welfare state regimes by taxes and transfers across countries. Empirical data on the redistribution of income across countries is rare. Researchers conducting cross-national studies of the welfare state have until very recently been forced to rely on such proxies as the share of social benefits in gross domestic product. Even fewer cross-national studies have examined the redistributive role of taxes and transfers. The lack of cross-national data for so central a variable as state redistribution has been changed recently by the work of Mahler and Jesuit (2006) and Jesuit and Mahler (2010). We elaborate on and update the work of Jesuit and Mahler.

Secondly, we confront results obtained by OECD (2008) with the results of the LIS database on the redistributive effect of social transfers across countries. The Luxembourg Income Study (LIS) offers micro-data on public and private sources of income that are comparable, detailed and accurate. Specifically, the LIS offers data on a large number of individual sources of income from both the private and public sectors. Moreover, the LIS data permit researchers to adjust for taxes and social insurance contributions assessed on income recipients. Using the LIS data set, it is possible to estimate direct redistribution for most developed countries. The intention of this paper is to offer an empirical analysis of state redistribution in 36 countries, with reference to micro-data on household income available from the Luxembourg Income Study. Our aim is to offer data on income redistribution that are more accurate, comparable, detailed and recent than those that have been used in past work.

Finally, we refine the method of Jesuit and Mahler. We undertake a more detailed study containing a simulation approach using LIS micro data which allow us to decompose income inequality through several taxes and social transfers. We develop a budget incidence simulation model to investigate to what extent several social transfers and taxes reduce income inequality in 36 countries, under a strong assumption that the absence of social transfers and taxes would not change individual behavior and labor supply (Frick et al., 2000; Palme, 1996). With respect to the inequality index, we use the Gini coefficient, and decompose the Gini in a comparative setting. We apply the most straightforward—and most common—way of measuring government redistribution, simply by comparing the income households report that they receive from private-sector sources with the income they receive after government transfers have been added and taxes and social insurance contributions deducted. The change in summary measures of inequality between pre- and post-government income represents direct government redistribution. For example, the mean of pre-government Gini indices of income inequality of the 36 countries in this study around 2004 was 0.47. After adding government transfers and deducting income taxes and social insurance contributions the Gini fell to 0.33, representing a Gini reduction of 14 points or 30 percent.

The paper is organized as follows. In Section 2 we summarize literature on the redistributive effect of taxes and transfers in LIS countries. Section 3 presents our research method. Section 4 provides a descriptive analysis of inequality and redistribution across 36 countries. Section 5 presents the empirical results of our detailed decomposition of the redistributive effect of social transfers and taxes across countries. Section 6 provides a research agenda and section 7 concludes the paper.

2. Income inequality and the redistributive effects of taxes and transfers across countries

The relationship between income inequality and redistribution in a cross-country perspective is not crystal clear (see on this Lambert et al, 2010). A large number of articles discuss the relationship between income inequality and redistribution among countries. Despite recent empirical evidence suggesting that there is more redistribution when pre-tax income inequality is high, it is claimed by others that societies with low pre-tax income inequality redistribute more than less equal societies. The main reason for the confusion stems from differences in measurement strategies. Indeed, with three distributions involved (pre-tax-transfer income, post-tax-transfer income, and the tax burden), and as there exist different inequality measures to sum up these distributions, not surprisingly the literature offers a plethora of research methods and empirical results. Below we shall briefly review the main ones, restricting us to Gini-based literature and applications, which are by far the most prevalent.

Vast literature analyze income distribution across countries, indicating that the role of social policy (taxes and transfers) is important in the magnitude of redistributing income.³ Korpi and Palme (1998) used data from LIS to study different types of welfare states. They illustrated that both the level of transfers and the targeting to the poor are important for reducing income inequality. Bradley et al (2003) divide the welfare states into three categories (Social Democratic, Christian Democratic and Liberal Democratic) to study government redistribution and distributive profiles of taxes and transfers. Their results indicate that welfare generosity does not have a significant effect on pre-tax and pre-transfer income inequality, but does have a positive impact on the total redistribution of incomes. By using LIS data for the mid-2000s, Pressman (2009) finds a larger proportion of middle-class households in countries with rather progressive national tax systems and relative generous government spending programs. With respect to the relationship between inequality and redistribution, the results are not always in line with each other. Kenworthy and Pontusson (2005) examined the trend in market income inequality and redistribution in OECD countries in the 1980s and 1990s, indicating that redistribution increased in most countries. However, welfare state policies compensated for this rise in market inequality across countries. With respect to income mobility, Morillas (2009) finds that market income inequality is negatively associated with the level of the redistributive effect of taxes and transfers across countries. Goudswaard and Caminada (2010) and Caminada and Goudswaard (2005) studied the redistribution of public versus private social programs which have opposite distributional effects.

The case for aggregate incidence studies was set down by Dalton (1936). From the studies in which this methodology has been implemented since research was initiated by Gillespie (1965). Of course, also critical literature on budget incidence analyses has emerged – but these criticisms leave the stylised conclusions intact; see a critical survey of efforts to measure budget incidence by Smolensky et al (1987). For example, the important issue of tax/transfer shifting is totally ignored in analyses on budget incidence in such a classical framework. However, models that include all behavioural links are beyond the scope of existing empirical work (Gottschalk and Smeeding, 1998:3). Therefore, researchers have restricted themselves largely to accounting exercises which

³ Among others, Brandolini and Smeeding (2007a and 2007b), Atkinson and Brandolini (2001), Smeeding (2000, 2004 and 2008), Gottschalk and Smeeding (1997, 1998 and 2000), Atkinson (2003), Ervik (1998), O'Higgins et al (1990), and Brady (2004).

decompose changes in overall inequality into a set of components (see on this Kristjánsson, 2011; Fuest et al, 2010; Paul, 2004). Despite the problem of tax shifting, analyses on statutory and budget incidence can be found for decades in literature on public finance.⁴

Most studies focus on overall redistribution; others have examined in more detail the redistributive effect of several social programs. For example, Plotnick (1984) calculates the redistributive impact of cash transfers in the US in 1967 and in 1974. Caminada and Goudswaard (2001 and 2002) performed a budget incidence analysis for the Netherlands to investigate the effect of transfers and taxes in 1981, 1991 and 1997. Ferraini and Nelson (2003) focus on the effects of taxation of social insurance in 10 countries around 1995, analyzing inter- and intra-country comparisons of income (re)distribution. Mahler and Jesuit (2006) divide government redistribution into several components: the redistributive effects from unemployment benefits, from pensions, and from taxes. They applied their empirical exercise for 13 countries with LIS-data around the years 1999/2000. We update and extend the analyses of Jesuit and Mahler by taking into account many more benefits and taxes, and we will apply a budget incidence analysis to a wider range of 36 countries with the most recent LIS data available (around 2004).

3. Research method

3.1 Measuring the redistributive effects of taxes and social transfers

Usually, the impact of social policy on income inequality is calculated in line with the work of Musgrave, Case and Leonard (1974), i.e. statutory or budget incidence analysis. A standard analysis of the redistributive effect of taxes and income transfers is to compare pre-tax-transfer income inequality and post-tax-transfer income inequality (OECD 2008: 98). Our measure of the redistributive impact of social security on inequality is straightforwardly based on formulas developed by Kakwani (1986) and Ringen (1991):

$$\text{Redistribution by taxes and social transfers} = \text{primary income inequality} - \text{disposable income inequality}$$

This formula is used to estimate the reduction in inequality produced by taxes and social transfers, where primary income inequality is given by a summary statistic of pre-tax, pre-transfer incomes and disposable income inequality is given by the same summary statistic of disposable equivalent incomes; see section 3.2 for more details. When calculating inequality indices for both primary and disposable income, people are ranked by their disposable incomes, so that the re-ranking effect is eliminated. Table 1 presents the framework of accounting income inequality and redistribution through various income sources; see Annex 1 for details on the LIS Household Income Components List.

⁴ See for example Dalton (1936), Musgrave and Tun Thin (1948), Gillespie (1965), Kakwani (1977a), Reynolds and Smolensky (1977a and 1977b), Kiefer (1984), Mitchell (1991), Silber (1994), OECD (2008) and analyses based on the Luxembourg Income Study database (some of them are listed in our references).

Table 1 The income inequality and redistribution accounting framework

Income components	Income inequality and redistributive effect
Gross wages and salaries + Self-employment income + cash property income + Occupational and private pensions + Private transfers + Other cash income = Primary income	Income inequality before social transfers and taxes
+ Social security cash benefits = Gross income	-/- Redistributive effect of social transfers = Income inequality before taxes
-/- Pay Roll (Mandatory payroll taxes) -/- Income taxes = Disposable income	-/- Redistributive effect of taxes = Income inequality after social transfers and taxes

Note: For France, Greece, Hungary, Italy, Mexico, Peru, Russia, Spain and Uruguay, the value of market income in the dataset is zero. Instead, we use net market income which is the sum of net wages and salaries, self-employment income and cash property income.

The measures of both pre- and post-social security income are far from ideal. At a conceptual level, no conceivable measure of pre-social security income could indicate what the income distribution would look like if social security did not exist. A comparison between the standard Gini index of post-tax-transfer income inequality and the hypothetical situation where social transfers are absent, other things being equal, shows that such transfers have an important redistributive effect that helps to reduce the number of people who are at risk of poverty.⁵ In the absence of all social transfers, the average poverty risk would be considerably higher than it is in reality. It should however be noted that the indicator of income inequality before social transfers must be interpreted with caution (Kim, 2000b; Nell, 2005). First, it is not taken into account that measures, like social cash transfers, can have the effect of raising the disposable incomes of households and individuals, namely transfers in kind, tax credits and tax allowances. Second, the pre-transfer inequality is compared to the post-transfer inequality keeping all other things equal – namely, assuming unchanged household and labor market structures, thus disregarding any possible behavioral changes that the situation of absence of social transfers would involve. However, behavioral responses – with the strongest effects on reducing work effort - have been at the heart of the policy debates shaping the evolution of antipoverty policy.⁶ Kim (2000b) showed that both the generosity and efficiency of the tax/transfer system may influence the level of pre-tax-transfer income inequality. Budget incidence calculations can only be seen as an approximation of the redistributive effects because the assumption that agents behave similar in situations with and without social transfers and social security. One may imagine the labor supply decision in absence of social transfers and social security. It is likely that in the absence of social transfers more people will work (more) thereby earning higher incomes and having consequences for income inequality. In essence, budget incidence analyses assume that labor supply decisions

⁵ Among others, see Behrendt (2002), Smeeding (2005), Förster (2000), Förster and Pearson (2002) and Förster and Mira d’Ercole (2005).

⁶ We refer to a seminal review by Danziger, Haveman and Plotnick (1981).

in a situation with social transfers and social security are equal to a situation without social transfers. So, this standard approach biases the redistributive effect of generous and/or targeted welfare systems. Our estimates for redistribution through taxes and transfers of each country should consequently be regarded as upper bounds.

3.2 Sequential decomposition of the Gini coefficient: partial effects of taxes and transfers

The Gini coefficient is expressed as follows (cf. Jenkins, 1999; updated 2010):

$$G = 1 + (1/n) - [2/n^2 \mu] \sum_{i=1}^n (n-i+1)y_i, \quad i = 1, 2, \dots, n \quad (1)$$

In formula (1), n denotes number of individuals, μ denotes average income of individuals, and y_i presents income of individual. The level of Gini coefficient is given by number of individuals, average income of individuals. Using expression (1), we are able to decompose the Gini coefficient of primary income into the Gini coefficient of disposable income and the redistributive effects of transfers and taxes. Income (inequality) can be measured with or without transfers and/or taxes.

$$y_i = y_i^{pri} + \alpha B_i - \beta T_i, \quad i = 1, 2, \dots, n, \quad \alpha, \beta \in \{0, 1\} \quad (2)$$

y_i^{pri} , B_i and T_i denote primary income of individual i , total transfer of individual i and total taxes of individual i , respectively. Depending on α and β , Individual income is determined by the sum of all cash incomes, such as wages, salaries, welfare benefits, public and private pensions, child and family allowances and so on, where we focus on social transfers and direct taxes. When $\alpha = 0$ and $\beta = 0$, the resulting inequality measure presents the Gini coefficient before taxes and transfers; if $\alpha = 1$ and $\beta = 1$, the measure corresponds to the Gini coefficient after taxes and transfers; if $\alpha = 0$ and $\beta = 1$ the measure shows the Gini coefficient after taxes but before transfers, which displays a world without social transfers. For $\alpha = 1$ and $\beta = 0$, inequality after transfers, but before taxes is measured.

In a more general expression, individual income can be shown as formula (3), consisting of primary income, at most m kinds of transfers and p types of taxes. B_{ik} show the k^{th} transfer of individual i , and T_{il} presents the l^{th} tax of individual i . When $\alpha_k = 1$, $\alpha_{-k} = 0$ ($\alpha_j = 0$ ($j \neq k$)) and $\beta_l = 0$, individual income includes primary income plus the k^{th} transfer; when $\alpha_k = 1$, $\beta_l = 1$ and $\beta_{-l} = 0$ ($\beta_q = 0$ ($q \neq l$)), individual income contains primary income plus all the transfers and the l^{th} tax, we explain why we choose this order later in section 3.3.

$$y_i = y_i^{pri} + \sum_{k=1}^m \alpha_k B_{ik} - \sum_{l=1}^p \beta_l T_{il}, \quad i = 1, 2, \dots, n, \quad k = 1, 2, \dots, m, \quad l = 1, 2, \dots, p, \quad \alpha_k, \beta_l \in \{0, 1\} \quad (3)$$

This allows us to calculate inequality (Gini) without a certain kind of transfers or tax, and consequently the partial redistributive effect of that transfer or tax. Likewise the redistributive effects of all income components within the trajectory between primary income inequality and disposable income inequality (like unemployment benefits, old age pension benefits, disability benefits, social assistance, income taxes, mandatory social contributions) can be calculated based on this formula.

We take a budget incidence approach to measure the redistributive effect of the welfare state, and we focus on the redistribution between individuals or households at one moment in time (not over the lifecycle). We apply the Reynolds-Smolensky (1977a and 1977b) measure of the redistributive impact of taxes and transfers to present the reduction in Gini coefficient from primary income (pri) to disposable income (dpi). The redistributive effect L can be expressed as (c.f. Creedy and Ven, 2001):

$$L = G_{pri} - G_{dpi} \quad (4)$$

L and G are the redistributive effect and the Gini coefficient of primary or disposable income. When moving from the pre-tax-transfer to the post-tax-transfer distribution, the re-ranking effect, R , is taken into account (Atkinson, 1979 and Plotnick, 1981).

$$R = G_{dpi} - C_{dpi} \quad (5)$$

Where C_{dpi} denotes the concentration coefficient. However, when income level is ranked by primary income rather than by disposable income, the re-ranking effect will be absent ($R = 0$). The total redistributive effect can be disentangled in several partial effects:

$$L_B = G_{pri} - G_{pri+B} \quad (6)$$

$$L_T = G_{pri+B} - G_{dpi} \quad (7)$$

L_B and L_T represent the partial redistributive effect of all benefit transfers B , and the partial redistributive effect of all taxes and social contributions T . Consequently, the decomposition in formula (6) and (7) will offer us a quantitative measure for the reduction in the Gini by social programs in a country.

In order to assess the effects of taxes and benefits on the overall redistribution we apply a sequential decomposition technique. This division is somewhat arbitrary since the choice of benchmark income affects the outcome. Applying the redistribution from, say, taxes on gross income rather than market income alters the outcome to some extent. Since taxes are levied on gross income (market income plus benefits), the redistributive effects may be underestimated. Nevertheless the logic of this decomposition of Gini is that taxes are applied to gross income and benefits to market income. This approach has been, among others, advocated by Kakwani (1986).

Our sequential decomposition approach of income inequality follows studies by Mahler and Jesuit (2004) and Mahler and Jesuit (2006), with inequality indices accounted sequentially in order to determine the effective distributional impact of different income sources. Other techniques of the decomposition of the Gini coefficient by income source can be found in the literature as well; see e.g. Lerman and Yitzhaki (1985), Stark et al (1986), Kim (2000a), Creedy and Ven (2001). For example the well-known Lerman and Yitzhaki's method derives the marginal impact of various income sources on overall income inequality.⁷ Fuest et al (2010) explore the redistributive effects of different tax benefit instruments in the enlarged European Union (EU) based on two families of approaches. When comparing both approaches, they lead to the same estimates of disposable income inequality, however, both lead to somewhat contradictory results with respect to the importance of benefits for redistributing income. Inequality analysis based on the *sequential accounting decomposition* approach suggests that benefits are the most important factor

⁷ See for 'descogini' in STATA (Lopez-Feldman, 2006).

reducing inequality in the majority of countries (e.g. Immervoll et al, 2005; Mahler and Jesuit, 2006; Whiteford, 2008). The *factor source decomposition* approach, suggested by Shorrocks (1982), however, suggests that benefits play a negligible role and sometimes even contribute slightly positively to inequality (e.g., Jenkins 1995; Jäntti 1997; Burniaux et al. 1998). On the contrary, here taxes and social contributions are by far the most important contributors to income inequality reduction. Fuest et al (2010) explain these partly contradictory results. The most important difference between the two approaches is that the accounting approach applies tax benefit instruments sequentially, whereas, the decomposition approach accounts for them simultaneously.

Although both approaches are used in the literature, studies analyzing the impact of tax benefit instruments based on the standard sequential accounting approach generally find rather intuitively straight forward results, i.e. that benefits are the most important source of inequality reduction in European countries. In order to assess the effects of taxes and benefits on the overall redistribution we (therefore) apply the sequential decomposition technique in line with the comparative work of Mahler and Jesuit (2006), and recent studies by Kristjánsson (2011) and Kammer and Niehues (2011). This choice for an sequential approach is somewhat arbitrary, but fits in a strand of empirical literature that systematically illustrate that social transfers significantly improve the economic conditions of families, especially in European countries, and that the distribution of disposable incomes in these societies become more equal with the existence of these types of provisions.

3.3 Sequential decomposition of the Gini coefficient: partial effects of different income sources

In order to disentangle the inequality even further by income source, the redistributive effect of several benefit transfers and taxes can be represented by formula (8) and (9):

$$L = G_{pri} - G_{dpi} \quad (4)$$

$$L_{Bk} = G_{pri} - G_{pri+B_k} \quad (8)$$

$$L_{Tl} = G_{pri+B} - G_{pri+B-T_l} \quad (9)$$

L , L_{Bk} and L_{Tl} represent the overall redistributive effect, the partial redistributive effect of a specific kind of transfer B_k , and the partial redistributive effect of an income tax T_l . Consequently, the decomposition in formula (8), and (9) will offer us an quantitative measure for the reduction in the Gini by social programs in a country.

It should be noted that the results to be obtained could be affected by the ordering effect, but we will correct for this. For example, the partial redistributive effect of a specific social transfer will be highest (smallest) when computed as the first (last) social program; see equation 3. The partial effects of these transfers in total redistribution could be computed in several orders. We consider every specific social transfer as the first program to be added to primary income distribution, and every direct tax as the first tax to be subtracted from gross income. In that case, the sum of all partial redistributive effects amount (a little) over 100 percent. We rescaled the redistributive effects of each program by applying an adjustment factor, which is defined as the overall redistribution given by formula (4) (= 100%) divided by sum of all partial redistributive effects of all programs (over 100%), in order to correct for an over-estimated effect.

3.4 Choice of income unit

The unit of analysis is an important issue in income distribution studies. It is evident that the ultimate source of concern is the welfare of the individual. However, an individual is often not the appropriate unit of analysis. E.g. children and spouses working at home do not have recorded income, but may nevertheless be enjoying a high standard of living as a result of income sharing with parents/spouses. How to solve the problem of the key question of the unit of analysis?

Traditionally, studies have used the household income per capita (or per member) measure to adjust total incomes according to the number of persons in the household. The last decades, equivalence scales have been widely used in the literature on income distribution (see Figini, 1998). An equivalence scale is a function that calculates adjusted income from income and a vector of household characteristics. The general form of these equivalence scales is given by the following expression: $W = \frac{D}{S^E}$, where W is adjusted income, D is income (disposable income), S is size

(number of persons in households) and E is equivalence elasticity. E varies between 0 and 1. The larger E , the smaller are the economies of scale assumed by the equivalence scales. Equivalence scales range from $E=0$ (no adjustment or full economics of scale) to $E=1$ (zero economies of scale). Between these extremes, the range of values used in different studies is very large, strongly affecting measured inequality.

Equivalence scale elasticity for the LIS database is set around 0.5. This implies that in order to have an equivalent income of a household of one person where D is 100, a household of two persons must have an income of 140 to have equivalent incomes. Alternatively an one-person household must have 70 percent of the total income of a two-person household to have equivalent income. In our comparative analysis we use this equivalence scale of LIS, where E is around 0.5. However, it has been shown that the choice of equivalence scales affects international comparisons of income inequality to a wide extend. Alternatively adjustment methods would definitely affect the ranking of countries, although the broad pattern remains the same (Atkinson et al, 1995:52).

3.5 Countries and other measurement issues

In empirical literature, the selection of countries and data-years differ due to the consideration of data quality. We apply a cross-national analysis using comparable income surveys for all countries of LIS around 2004. LIS micro data seems to be the best available data for describing how income inequality and the redistributive effects of taxes and transfers vary across countries (Nolan and Marx, 2009; Smeeding, 2008). LIS data contains information for 36 countries for one or more than one year of data (from wave I to wave VI), allowing researchers to make comparisons in a straightforward manner, and the information is still updating and expanding. This paper uses the data of all countries in LIS. In this paper we restrict ourselves to the latest data year available (around 2004) to analyze redistribution of social transfers and taxes. Countries included in LIS come from Europe, North America, the Far East and Australia: Australia, Austria, Belgium, Brazil, Canada, Colombia, Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Guatemala, Hungary, Ireland, Israel, Italy, Korea, Luxembourg, Mexico, Netherlands, Norway, Peru, Poland, Romania, Russia, Slovak Republic, Slovenia, Spain, Sweden, Switzerland, Taiwan, the United Kingdom, the United States, and Uruguay.⁸

⁸ It should be noted that Taiwan is regarded as a district of China, while in this comparative study we simply refer to Taiwan (as coded by LIS).

From nearly 300 variables in the dataset, we choose those related to household income (all kinds of income sources), total number of persons in a household and household weight (in order to correct sample bias or non-sampling errors) to measure income inequality and the redistributive effect across countries. In line with LIS convention and the work of Mahler and Jesuit (2006), we have eliminated both observations with zero or a missing value of disposable income from LIS data. Household weights are applied for calculation of Gini coefficients.

It should be noted that there have been controversial arguments regarding the issues in the measurement of income inequality. These arguments have their own merits and shortcomings, and there has been little professional consensus among researchers with regard to the theoretical superiority of a particular way of measuring inequality. Moreover, the availability of reliable data restricts the possibilities for conducting empirical research, which is especially problematic in cross-national studies. The aim of this paper is *not* to review definitional issues that arise in assessing the extent of, and change in, income inequality in Western industrialized countries. We simply refer to a vast literature on the sensitivity of measured results to the choice of income definitions, inequality indices, appropriate equivalence scales, and other elements that may affect results in comparative research.⁹

4. Inequality and redistribution across LIS countries: A descriptive analysis

4.1 Inequality across countries

This section reviews the evidence on cross national comparisons of annual disposable income inequality over 36 nations. This section is mainly descriptive and relies on the empirical evidence LIS and from OECD (2008) for the levels of income inequality around the mid 2000s. Levels of inequality can be shown in several ways, e.g., by Lorenz curves, specific points on the percentile distribution (P10 or P90), decile ratios (P90—P10), and Gini coefficients or many other summary statistics of inequality. All (summary) statistics of inequality can be used to rank income inequality in LIS countries, but they do not always tell the same story.

Figure 1 shows the Gini coefficient. Countries are listed in order of their Gini of disposable income from smallest to largest. The obvious advantage of the presentation of inequality by summary statistics like the Gini coefficient is its ability to summarize several nations in one picture.

⁹ Among others, see Atkinson (1970, 1979, 1987 and 2003), Champernowne (1974), Kakwani (1977b), Hagenars and De Vos (1987), Coulter (1989), Atkinson et al (1995), Behrendt (2000), Gottschalk and Smeeding (1997 and 2000), Marcus and Danziger (2000), Atkinson and Brandolini (2001 and 2006), Caminada and Goudswaard (2001 and 2002), Förster and Pearson (2002), Smeeding (2005 and 2008), Förster and Mira d'Ercole (2005), OECD (2008) and (other) papers listed in our reference section using data from the Luxembourg Income Study. Recent comprehensive reviews on methodological assumptions underlying international levels and trends in inequality are found in Brandolini and Smeeding (2007 and 2008).

Figure 1 Disposable and primary income inequality across LIS countries around 2004

Source: own calculations based on LIS

The lowest income inequality is found in the Nordic countries, while Uruguay, Russia, Mexico, Guatemala, Peru and Columbia are the most unequal nations. Figure 1 indicates that a wide range of inequality exists across 36 LIS nations, with the nation with the highest inequality coefficient (Columbia) over twice as high as the nation with the lowest coefficient (Denmark).

With respect to income inequality after social transfers and taxes, there are 24 countries with the Gini coefficient below average (0.33). Denmark, Sweden, Slovak Republic and Slovenia have rather low values around 0.24, in line with the results in OECD (2008), followed by other 12 countries (Finland, Norway, Netherlands, Czech Republic, Switzerland, Luxembourg, Austria, Romania, Germany, Belgium, France and Hungary) with Gini coefficients between 0.25 and 0.30. Above average inequality is found in 12 countries (Italy, Estonia, the United Kingdom, Israel, the United States, Uruguay, Russia, Mexico, Brazil, Guatemala, Peru and Colombia).

The pattern of primary income inequality (before social transfers and taxes) is quite different from disposable income inequality. Russia, Brazil, and Belgium have the highest level of primary income inequality, with values around 0.55. Taiwan, Korea, Romania and Switzerland have rather low levels of primary income inequality, below 0.40. The redistributive effect of taxes and social transfers differ considerably across countries. The highest level of redistribution is found in Belgium, Hungary and Finland, while redistribution is rather small in Peru and Colombia. This cross country difference in the redistributive effect will be analyzed in section 4.2.

4.2 The redistributive effect of taxes and transfers

Several studies focused on the impact of income components on overall inequality (Shorrocks, 1983; Lerman and Yitzhaki, 1985; Jenkins, 1995; Breen et al, 2008). These suggest that income taxes and social benefits are important sources of reducing household income inequality. Figure 2 shows the overall redistribution across countries and the disaggregated effects of social transfers and taxes based on formula (6) and (7). On average, the share of social transfers play a major role of 85 percent in the total reduction of inequality, while taxes take account for 15 percent of total reduction of income inequality. According to LIS income surveys, income taxes and mandatory payroll taxes are involved in the redistribution of taxes, rather than indirect taxes. For some countries, such as Hungary, Italy, Mexico, Peru, Russia, Slovak Republic, Slovenia and Uruguay data of taxes are not available in the dataset.

Figure 2 Redistributive effect of taxes and transfers across LIS countries around 2004

Note: For Hungary, Italy, Mexico, Peru, Russia, Slovak Republic, Slovenia and Uruguay data for taxes are not available.

Source: own calculations based on LIS

Belgium, Hungary, Finland, Germany, Poland, Sweden and Czech Republic have high levels of total redistribution, while Korea, Taiwan, Mexico, Guatemala, Colombia and Peru have a rather small extent of overall redistribution. In view of total redistribution, Guatemala is one of the countries having a rather low level of total redistribution. However, this inequality reduction is mainly achieved by taxes. Besides Guatemala, only in a few countries taxes are important in equalizing incomes: the United States, Israel, and Canada. Generally speaking, redistribution of income in most countries relies to a large extent on social transfers. This relative effect of social transfers and taxes in total redistribution is presented in Figure 3 (countries are listed according to the reduction of income inequality by taxes).

Figure 3. Relative redistributive effect of taxes and transfers across countries around 2004

Note: For Hungary, Italy, Mexico, Peru, Russia, Slovak Republic, Slovenia and Uruguay data for taxes are not available.

Source: own calculations based on LIS

Note that the partial effect of taxes is negative for Colombia and for Switzerland. The negative contribution for Switzerland is caused by tax competition (Kirchgässner and Pommerehne, 1996; Feld 1999). In this country it appears to be difficult to levy redistributive taxes from the rich and mobile persons to the poor. As a result the amount of taxes paid by rich people is relatively low.

4.3 Redistribution, budget size and targeting

Considering the redistributive effect of social benefits, scholars have distinct between programs' size and the extent to which they are targeted toward low-income groups by means-testing. In a seminal paper by Korpi and Palme (1998: 663), they have posited a "paradox of redistribution" whereby "the more we target benefits to the poor . . . the less likely we are to reduce poverty and inequality." The paradox arises from the fact that highly targeted programs have the support of a small and isolated political base. As they put it, targeted programs offer "no rational base for a coalition between those above and below the poverty line. In effect, the poverty line splits the working class and tends to generate coalitions between better-off workers and the middle class against the lower sections of the working class" (Korpi and Palme, 1998: 663). Comprehensive programs, on the other hand, even when they are organized according to social insurance principles, tend to encourage coalitions between the working and middle classes that leave low-income groups less isolated.

With this background in mind, it is useful to explore empirically these two aspects of transfers with reference to the LIS database. Is redistribution associated with transfers' overall size or with their target efficiency? Is there, as is often suggested, a tradeoff between the two? Using LIS

micro data it is possible to calculate a measure of the average value of social transfers as a percentage of households' pre-tax income: the larger the value, the greater the share of total income that derives from transfers. It is also possible to calculate a summary index of the degree to which transfers are targeted toward low-income groups. This is done by applying Kakwani's (1986) 'index of concentration' to transfers. This index takes on the value of -1.0 if the poorest person gets all transfer income, 0 if everybody gets an equal amount, and +1.0 if the richest person gets all transfer income (cf. Korpi and Palme, 1998: 684). Figures for the size and target efficiency of social benefits are calculated for all 36 LIS countries are reported in Figure 4; see more details in Table 2.

As is shown, there is indeed considerable variance among developed countries in the average size of social benefits relative to total household income, ranging from 3.1% to 35.7%. In rich LIS countries, Austria, Finland and France achieve the highest budget size of transfers (above 25%), followed by Germany, Greece, Italy, Luxembourg, Netherlands, Norway, Spain and Sweden with values between 20% and 25%, while Belgium and the U.S. have the lowest level less than 10%. As for target efficiency, it is more diverse across countries. France and Italy have a rather high budget size of transfers with transfer programs slightly regressive. Finland, Germany, the Netherlands and Sweden have low target efficiency, but high social expenditures. Australia and the United Kingdom show high figures for transfer targeting although with a modest redistributive budget size (less than 15%). The United States is one of the countries with rather low social transfers, also with a quite low target efficiency. Interestingly, Canada, at the very bottom of our list of budget size, achieves a high target efficiency among rich countries.

Figure 4. Redistribution, budget size and targeting across 36 LIS countries around 2004

Source: own calculations based on LIS

The budget size of transfers plays a very important role on overall redistribution, which is confirmed by a simple regression analysis in Figure 4 Panel (a). The estimated coefficient of the budget size is statistically significant. Further more, target efficiency is also strongly and negatively significant with total redistribution (see Panel (b)), which is in line with the claim of

Korpi and Palme that greater use of transfer targeting yields less redistribution. However, it should be noted that our analysis is based on 36 LIS countries. When we restrict our analysis to the twenty wealthiest countries of LIS, both correlations disappear. Redistribution of incomes across countries does not correlate with both the budget size and the target efficiency. This little or no indication of a relationship between targeting and redistribution is in line with recent work of Kenworthy (2011: Chapter 6, page 2-4).

Figure 5. Redistribution, budget size and targeting across 20 rich LIS countries around 2004

4.5 Sensitivity analysis

While even the LIS-data are by no means perfect, they produce some consistent patterns. The range of income inequality among LIS and OECD countries seems very wide at any point in time. Moreover, in spite of differences in the measurement of income inequality and the databases used, most studies have consistently found that there is a large difference in inequality among welfare states. Reports on inequality profiles for EU15 and other OECD countries for the latest data year available from OECD (2008) also consistently show – in general – Scandinavian and Benelux countries have the lowest income inequality, followed by continental European countries. Anglo Saxon welfare states have relatively higher inequality. Among them, the level of income inequality is high in the United States.

Table 3 compares Gini coefficients (before and after social transfers and taxes) around 2004 from the OECD database with figures from LIS (2011), which are completely in line with our calculations. From the 41 countries listed in Table 3, 20 countries are adopted in both the OECD-database and the LIS-database. Note that disposable income inequality data across countries of OECD-data and LIS-data are highly correlated (around 0.93). Correlation coefficients for primary income and for redistribution are somewhat lower (resp. 0.75 to 0.78). For most countries the difference in primary income inequality from OECD and from LIS do not exceed 3 percentage points, with exceptions for Belgium, Finland, Germany, Ireland, Italy, The Netherlands, Poland, Slovak Republic and the United Kingdom. What could explain these differences?

First and foremost, it is because the difference between income surveys. LIS micro data are predicated on different surveys across countries, for instance, Socio-Economic Panel (SEP) / NL ECHP (NL94, NL99, NL04) in the Netherlands, Current Population Survey (CPS) in United States, Survey of Income and Housing Costs (SIHC) in Australia. From those surveys, LIS staff refined and formalized rules used to classify variables, offering comparable micro dataset. Computations in OECD dataset are based on the OECD income distribution questionnaires. Therefore, the sample of surveys is not the same, leading to the different values of income inequality and the redistributive effect of taxes and transfers.

Second, there are minor differences with regard to the methodology applied. The concept of disposable income is quasi-identical between both data sources (OECD, 2008: 153). However, the equivalence scale used by LIS differs slightly from the one used by the OECD, giving a somewhat higher weight to additional household members and distinguishing between adults and children. LIS equivalent scale equals to the square root of the number of persons in the household while OECD modified equivalent scale = $1 + 0.5 \times \text{number of other adult members} + 0.3 \times \text{number of children below 14}$ (OECD original equivalent scale = $1 + 0.7 \times \text{number of other adult members} + 0.5 \times \text{number of child below 14}$).

Third, it is because the definition of primary income, and the way income inequality before transfers and taxes is measured. Using LIS data, the degree of redistribution is calculated by comparing Gini coefficients on the basis of primary income and on the basis of gross income, in which primary income is considered as the sum of market income, private transfers and other cash income. With respect to pre-government income inequality using OECD data, it depends on market income. Consequently, the level of income disparity and overall redistributive effect differs when data is used from the LIS dataset and from the OECD dataset.

Table 3 OECD versus LIS: Income inequality and Redistribution across countries

Country	OECD-data around 2004				LIS-data around 2004

Source: OECD (2008), LIS (2011) and own calculation.

Although the way of measuring income inequality differs to some extent in the LIS-dataset and the OECD-dataset, the general pictures from both datasets are almost the same. Table 4 ranks 20 common countries in LIS-data and OECD-data from low to high for all data variables around 2004. The smallest disposable income disparity exists in Denmark and Sweden, while the largest value is found for the United States, independent of the data source used. With respect to the reduction of income inequality by taxes and transfers, Belgium achieves the highest level, while Korea shows the lowest value, again independent of the data source used. Both data sets rank Korea on top the list for the lowest primary income inequality. The largest value for primary income inequality is found for Belgium according to LIS, while OECD-methodology points at Poland.

To conclude: relatively high levels of primary income inequality are found for Belgium, Poland, and Italy, while low values are found for Korea, Denmark, and Finland. With respect to disposable income inequality, high indices are found for the United States, the United Kingdom, Poland and Italy, while low Gini coefficients are found for Denmark and Sweden. The redistributive effect of taxes and transfers is relatively high in Belgium and Germany, while the redistributive effect is rather low for Korea and the United States.

Table 4 Ranking of common countries in LIS and OECD dataset

	GINI pri		GINI dpi		Redistribution

5. Decomposition of the redistributive effect of social transfers and taxes across LIS countries around 2004: an empirical analysis

This section provides detailed results of the redistributive effect of welfare state regimes across a selection of our 36 countries based on the most recent wave of LIS. We elaborate on the work of Jesuit and Mahler (2006). However, we refine their Fiscal Redistribution approach. LIS data allow us to decompose the trajectory of the Gini coefficient from primary to disposable income inequality in several parts: we will distinguish 11 different social benefits and several income taxes and social contributions in our empirical investigation across countries. We calculate the following (partial) redistributive effects, based on formula (8) and (9) and based on the LIS household income components list (see Annex 1 for more details): sickness benefits, occupational injury and disease benefits, disability benefits, state old-age and survivors benefits, child/family benefits, unemployment compensation benefits, maternity and other family leave benefits, military/veterans/war benefits, other social insurance benefits, social assistance cash benefits, near-cash benefits, mandatory payroll taxes and income taxes.

Special attention needs the treatment of pensions. Public pension plans are generally seen as part of the safety net, generating large antipoverty effects through transfers and taxes (contributions). So, state old-age pension benefits will be included in our analysis on redistribution. But countries differ to a large extent in public versus private provision of their pensions (OECD, 2008:120). Occupational and private pensions are not antipoverty programs per se, although they too have a significant effect on redistribution when pre-tax-transfer inequality and post-tax-transfer inequality are measured at one moment in time, particularly among the elderly. The standard approach treats contributions to government pensions as a tax that finances the retirement pensions paid out in the same year, while contributions to private pensions are effectively treated as a form of private consumption. This may affect international comparisons of redistribution effects of social transfers and taxes. Overcoming this bias requires a choice: should pensions be earmarked as market income or as a transfer? We deal with this bias rather pragmatically by following LIS Household Income Variables List: occupational and private pensions are earmarked and threaded as market income (see Table 1, and Annex 1, Table A2).

To illustrate the idea of decomposition disposable income inequality, Table 5 presents the results of our accounting exercise for the mean of all 36 LIS countries. Interestingly, only three programs account for 62 percent of total redistribution: public old age pensions and the survivors scheme (46%), social assistance (7%) and the disability scheme (9%). Income taxes account for another 15 percent of total redistribution. Other social benefit programs and contributions seem to have a rather limited redistributive effect; together they account for only 23 percent of the reduction in income inequality through taxes and transfers.

- j Mandatory contributions for self-employment; Mandatory employee contributions.

Source: own calculations based on LIS

It should be noted that our results are hardly affected by the ordering effect. Following equation (8), the partial redistributive effect of a specific social transfer will be highest (smallest) when computed as the first (last) social program; see section 3.3. A sensitivity analysis shows that changing the order of adding a specific benefit to primary income (or subtracting tax from gross income) does change the partial effect of this transfer (or tax) in total redistribution only slightly. In case we consider a specific social transfer as the last (instead of the first) program to be added to primary income distribution, the computed partial redistributive effect changes up to 1%-point at the highest.

We have done the accounting exercise presented in Table 5 for all 36 countries listed in the LIS database; see Annex 2 for details. Here we only present the results of the decomposition of the trajectory of the Gini coefficient from primary to disposable income inequality for groups of countries. We clustered all countries to be a representative for Anglo-Saxon countries, Continental European countries, Nordic countries, according to Esping-Anderson types of welfare states (Esping-Andersen and Myles, 2009; Arts and Gelissen, 2002; Bonoli, 1997; Ferrera, 1996). Anglo-Saxon countries have low social expenditure as a percentage of GDP and low contributions as a percentage of social expenditure. Interventions from government are limited in the free market and the influence of wage negotiation is rather weak, comparing with e.g. European countries. These countries have high social expenditures and high contributions; social insurance systems are mainly financed by income taxes. Social transfers are generous as a rule. Nordic countries have high social expenditures and low contributions. High income taxes are combined with high social transfers and public investment. Southern European countries have low social expenditures and high contributions. Their developments of economic systems are similar to continental European countries (social market economy model), while their welfare states are a bit more similar to Anglo-Saxon countries.

Table 6 presents the results of the decomposition of income inequality and the redistributive effect of several social transfers and taxes and contributions for 36 LIS countries around 2004. Some benefits or taxes do not have any redistributive effect. The meaning of this is twofold. First, such a benefit scheme does not exist in a specific country and/or data is not available in LIS (represented as '-'). Second, such a program exist, but does not have a redistributive effect, because the social expenditures of this program is rather low or the program is distributed equally among the population (noted as 0%).

Source: own calculations based on LIS

In most countries two dominant income components account for above 50 to 60 percent of total reduction in income inequality: the public old age pensions and the survivors scheme, and the income taxes. Of course, the dominant effect of old age pensions makes sense, since the elderly have in general no income from work. However, cross country differences are huge. For example, in Southern European Countries the public old age benefits account for over 80 percent of total redistribution, while these figures are much lower for Anglo-Saxon Countries (20-34%), for Nordic Countries (31-48%), for Continental European Countries (47-57%) with the exception for Switzerland (79%), and for Central Eastern European Countries (54-70%) with the exception for Slovenia (79%).

In Anglo-Saxon Countries income taxes play a major role (above 30%) compare to other countries (with the exception the United kingdom). The United States is a special case, because the income tax contributes for a relatively large part (38%) to the reduction of income inequality between primary and disposable incomes. Their earned income tax credit (EITC) is targeted towards the poor, which makes the US tax system rather progressive. Also the redistributive effect of social assistance in the Anglo-Saxon Countries is relatively high in a comparative setting (9-28%), with Australia as an exception.

Child and family benefits are important in Anglo-Saxon Countries (6-13%), in Continental European Countries (4-12%), and in Central Eastern European Countries (5-12%). In Nordic Countries also a variety of other social programs contribute to the reduction of inequality, especially the disability scheme (9-15%). Remarkably, across countries all other social benefit programs seems to have rather limited redistributive effects, although the unemployment compensation benefits do have some effect too.

The group of other LIS Countries is rather mixed. It is hard to draw a line through the observed decomposed elements of income inequality across these countries. See Table 6.

6. Future research

Our analysis on the disentanglement of income inequality and the redistributive effect of social transfers and taxes in 36 LIS countries so far was restricted to one moment in time (Wave VI of LIS). However, LIS data allow us to compare fiscal redistribution across the developed countries over the last three decades. Our approach and the use of LIS data will be of additional value to future researchers after we have created time-series across countries of detailed fiscal redistribution between the 1970s and the mid-2000s. Our Annex 3 offers a data set with a number of measures of fiscal redistribution in the developed countries, drawing upon data from 177 Luxembourg Income Study surveys conducted in 36 countries between 1967 and 2006. In this dataset we have computed several results, namely income inequality before social transfers and taxes, income inequality after social transfers and taxes, the overall redistributive effect, the average size of social transfers as a proportion of households' pre-tax income, a summary index of the degree to which transfers are targeted toward low-income groups, the partial effect of redistribution by several social transfers, and the partial effect of redistribution by several income taxes.¹⁰ Research can employ these data in addressing several important research issues. Among

¹⁰ Our results are in line with or within narrow bandwidths with results from LIS. LIS Key Figures presents slightly other figures for Gini disposable income for only 15 out of 177 datasets. The results on

the most commonly addressed questions in the empirical literature on the welfare state concerns the sources of variance across countries and over time in the extent and nature of fiscal redistribution. Changes (in the generosity) of welfare states can be linked to (changes in the fiscal redistribution). Best-practice among countries can be identified and analyzed in more detail. In exploring the causes and effects of welfare state redistribution in the developed world, the literature has increasingly moved towards more disaggregated measures of social policy, an enterprise in which the LIS, with its detailed data on taxes and a large number of individual social benefits, offers a rich source of information. LIS data are detailed enough to allow an in depth analysis on programs' size and the extent to which they are targeted toward low-income groups. Is redistribution associated with transfers' overall size or with their target efficiency? Is there, as is often suggested, a tradeoff between the two?

In near future research could focus on households with very low income as well—those in poverty. The budget incidence approach based on LIS data allows us to employ all kind of cross-national analyses.¹¹ How well is social expenditure targeted to the poor? Moreover, with LIS data on fiscal redistribution we are able to analyze differences in anti-poverty approaches of countries (Europe versus the United States) and/or to judge the effectiveness of poverty reduction by taxes and transfers across countries.

Over time the use of household income survey data in policy analyses increased. Today the capacity to describe and analyze the effects of existing policy and simulate the effects of changes in policy is well-established in most nations with elaborate welfare states. The next step in improving policy analysis can come from moving to a cross-national focus using comparable income surveys on fiscal redistribution in a number of countries. To this end, we are able to assemble a databank of fiscal redistribution that can be used by scholars and policy analysts to study the effects of different kinds of programs on poverty, income adequacy in retirement, and the distribution of financial well-being generally. This project is named Leiden LIS Budget Incidence Database on Fiscal Redistribution Across Countries and is available at www.hsz.leidenuniv.nl.

7. Conclusion

In this paper, we have investigated income distribution and redistributive effect attributed to social transfers and taxes across 36 countries around 2004, based on the micro household income data from LIS. We have provided primary and disposable income inequality, total and disaggregated redistributions in a comparative way, across much more countries than that have been studied before, offering an accurate, detailed picture of redistribution of incomes through taxes and transfers across social welfare states.

Different social policies bring different types of welfare systems, leading to various outcomes in the income distribution. Among all LIS countries listed in this paper, Denmark and Sweden have the smallest income disparity, while Peru and Colombia have the largest. Nordic countries show the most equally distributed disposable incomes and primary incomes, comparing to the countries

redistribution are in line with Jesuit and Mahler (2004), and Mahler and Jesuit (2006). See our downloadable Leiden LIS Budget Incidence Fiscal Redistribution Dataset.

11 In line with our earlier work. See Caminada and Goudswaard (2009 and 2010); Caminada et al (2011) and Caminada and Martin (2011).

in other kinds of welfare states. On average, large primary income disparity exists in Anglo-Saxon countries. Generally speaking, European countries achieve lower levels of income inequality than other countries.

With respect to redistributive effect, our budget incidence analysis indicates that the pattern is diverse across countries. The largest redistribution is found for Belgium, while Colombia and Peru show rather limited overall redistributive effects. On average transfers reduce income inequality by over 85 percent, while taxes account for 15 percent of redistribution. Tax systems in Switzerland and Colombia are regressive. Transfers still play a dominant role in most countries in reducing initial income disparities. Among all welfare states, Continental European countries (Belgium, France, Germany, Luxembourg and the Netherlands) achieve the highest level of the reduction of initial income inequality.

Mahler and Jesuit (2006) divided government redistribution only into three general components (from unemployment benefits, from pensions, and from taxes) and applied their analysis to 13 countries. We update and extent their analyses by taking into account many more benefits and taxes, and we have applied a budget incidence analysis to all 36 LIS countries with the most recent LIS data (around 2004). As far as social programs is concerned, in most countries two dominant income components account for above 50 to 60 percent of total reduction in income inequality: the public old age pensions and the survivors scheme, and the income taxes. For example, in Southern European Countries the public old age benefits account for over 80 percent of total redistribution, while these figures are much lower for Anglo-Saxon Countries (20-34%), for Nordic Countries (31-48%), for Continental European Countries (47-57%), and for Central Eastern European Countries (54-70%). In Anglo-Saxon Countries income taxes play a major role (above 30%) compare to other countries (with the exception the United kingdom). Also the redistributive effect of social assistance and child and family benefits in the Anglo-Saxon Countries are relatively high in a comparative setting (9-28%). In Nordic Countries also a variety of other social programs contribute to the reduction of inequality, especially the disability scheme (9-15%). Remarkably, across countries all other social benefit programs seem to have rather limited redistributive effects, although the unemployment compensation benefits do have some effect too.

Annex 1: LIS Household Income Components List

Luxembourg Income Study contains information for a large number of countries for one or more than one year of data from wave I (the earliest year is in 1967) to wave VI (the latest year is in 2006). LIS contains information of income microdata in LIS database, wealth microdata in LWS database and country-level poverty and inequality indicators in LIS Key Figures. Research on income distribution across countries attracted many attentions, with the rapid development of comparable data from LIS. As a “public good”, the LIS project is funded on a continuing basis by its member countries’ national science foundations and social science research foundations (Smeeding, 2008). LIS database contains variables both at a household level and at a personal level, in which personal files also include labor market variables. This paper focuses on income information at the household level.

Below we provide the household income components list, by variable name and meaning. More specific explanation of the data can be found in the user-friendly LIS website (<http://www.lisdatacenter.org/>). In Table A3 household income is divided into 8 parts: wages and salaries, self-employment income, property income, occupational and private pensions, social security cash benefits, private transfers, other cash income and income tax (and employee social security contributions). In each part, there are more specific income sources, which is very helpful for studies focusing on different elements of income. For instance, v4 and v5 show self-employment income; v16 – v26 report social security cash benefits; v7, v11 and v13 provide income taxes and mandatory payroll taxes. There are also four kinds of widely used income definitions: factor income, market income, gross income and disposable income. Table A2 provides household aggregated income sources. Using those aggregated variables, it is more convenient to process and present income distribution results.

In this paper we compute five kinds of results, namely income inequality before social transfers and taxes, income inequality after social transfers and taxes, the overall redistributive effect, the partial effect of redistribution by several social transfers and the partial effect of redistribution by several income taxes (see for a specification in Table A2). In calculating pre-government income inequality, we use primary income, which consists of market income (mi), Alimony/child support (v34), regular private transfers (v35) and other cash income (v36); in calculating post-government income, we use net disposable income (dpi). In order to obtain redistributive effect, besides the variables mentioned above, we use total social transfers (SOCTRANS), mandatory payroll taxes (PAYROLL) and income taxes (v11). For some countries (Belgium, France, Greece, Hungary, Italy, Mexico, Peru, Russia, Spain, Uruguay), we use net wages and salaries (v1net) instead of gross wages and salaries (v1) as a component of market income (v1+v4+v5+v8+v32+v33), due to v1 is not available in the dataset. In addition, we use the number of persons in a household (D4) and household weight (HWEIGHT) in LIS dataset so as to obtain equalised income and weighted results.

Table A1 LIS income distribution indicator list

Income Distribution Indicator	Redistribution Measurement	Specific Income Source
Gini (pri)		Primary Income (V1+V4+V5+V8+V32+V33+V34+V35+V36)
Transfers Redistribution	Gini (pri)-Gini (pri+trans)	
Gini (pri+trans)		Primary Income + social transfers (V1+V4+V5+V8+V32+V33+V34+V35+V36+V16+V17+V18+V19+V20+V21+V22+V23+V24+V25+V26)
Taxes Redistribution	Gini (pri+trans)-Gini (dpi)	
Gini (dpi)		Net disposable Income (V1+V4+V5+V8+V32+V33+V34+V35+V36+V16+V17+V18+V19+V20+V21+V22+V23+V24+V25+V26-V7+V13-V11)
Overall Redistribution	Gini (pri)-Gini (dpi)

a Including ordering effect. The partial redistributive effect of a specific social transfer will be highest (smallest) when computed as the first (last) social program. The partial effects of these transfers in total redistribution could be computed in several orders. We consider every specific social transfer as the first program to be added to primary income distribution, and every direct tax as the first tax to be subtracted from gross income. In that case, the sum of all partial redistributive effects amount (a little) over 100 percent. We rescaled the redistributive effects of each program by applying an adjustment factor, which is defined as the overall redistribution given by formula (4) (100%) divided by sum of all partial redistributive effects of all programs (over 100%), in order to correct for an over-estimated effect.

a Including ordering effect. The partial redistributive effect of a specific social transfer will be highest (smallest) when computed as the first (last) social program. The partial effects of these transfers in total redistribution could be computed in several orders. We consider every specific social transfer as the first program to be added to primary income distribution, and every direct tax as the first tax to be subtracted from gross income. In that case, the sum of all partial redistributive effects amount (a little) over 100 percent. We rescaled the redistributive effects of each program by applying an adjustment factor, which is defined as the overall redistribution given by formula (4) (100%) divided by sum of all partial redistributive effects of all programs (over 100%), in order to correct for an over-estimated effect.

Annex 3 Budget Incidence Fiscal Redistribution Dataset – LIS Waves I – VI, 1970-2006

Aim

Leiden Budget Incidence Fiscal Redistribution Dataset presents the disentanglement of income inequality and the redistributive effect of social transfers and taxes in 36 LIS countries for the period 1970-2006 (Waves I - Wave VI of LIS). This dataset allow researchers and public policy analysts to compare fiscal redistribution across developed countries over the last three decades. Research may employ these data in addressing several important research issues. Among the most commonly addressed questions in the empirical literature on the welfare state concerns the sources of variance across countries and over time in the extent and nature of fiscal redistribution. Changes (in the generosity) of welfare states can be linked to (changes in the fiscal redistribution). Best-practice among countries can be identified and analyzed in more detail. In exploring the causes and effects of welfare state redistribution in the developed world, the literature has increasingly moved towards more disaggregated measures of social policy, an enterprise in which the Leiden Budget Incidence Fiscal Redistribution Dataset, with its detailed data on taxes and a large number of individual social benefits, offers a rich source of information. Research could focus on households with very low income as well—those in poverty. The budget incidence approach based on LIS data allow researchers to employ all kind of cross-national analyses. How well is social expenditure targeted to the poor? Moreover, with LIS data on fiscal redistribution research is able to analyze differences in anti-poverty approaches of countries (Europe versus the United States) and/or to judge the effectiveness of poverty reduction by taxes and transfers across countries.

The assembled databank of fiscal redistribution can be used by scholars and policy analysts to study the effects of different kind of programs on poverty, income adequacy in retirement, and the distribution of economic well-being generally.

Origin of the idea

The original database on Fiscal Redistribution based on LIS date was initiated by Jesuit and Mahler in 2004 ([LIS Working Paper #392](#)). Leiden Budget Incidence Fiscal Redistribution Dataset refines, updates and extent their Fiscal Redistribution approach. LIS data allowed us to decompose the trajectory of the Gini coefficient from primary to disposable income inequality in several parts: the dataset distinguish 11 different benefits and several income taxes and social contributions across countries.

Jesuit and Mahler divided overall government redistribution only into 3 components: the redistributive effects from unemployment benefits, from pensions, and from taxes. They applied their empirical exercise for 13 countries with LIS-data around the years 1999/2000. The launch of Leiden Budget Incidence Fiscal Redistribution Dataset covers many more benefits and taxes, is applied to a much wider range of 36 countries using the most recent LIS data available.

Dataset

This data set offers a number of measures of fiscal redistribution in the developed countries, drawing upon data from 177 Luxembourg Income Study surveys conducted in 36 countries between 1967 and 2006. In this dataset we have computed five kinds of results, namely income inequality before social transfers and taxes, income inequality after social transfers and taxes, the overall redistributive effect, the partial effect of redistribution by several social transfers and the partial effect of redistribution by several income taxes (see for a specification below). Specifically, we have computed:

- 1) A measure of overall fiscal redistribution, as reflected in the difference between the Gini indexes of pre-tax-transfer primary income and post-tax-transfer disposable income. We offer measures of both absolute fiscal redistribution ($Gini_{pri} - Gini_{dpi}$) and relative fiscal redistribution ($(Gini_{pri} - Gini_{dpi}) / Gini_{pri}$).
[Table A1 in Excel Spreadsheet]
- 2) The shares of absolute and relative fiscal redistribution resulting from direct taxes and social transfers.
[Table A2 in Excel Spreadsheet]
- 3) The average size of social transfers as a proportion of households' pre-tax income, and a summary index of the degree to which transfers are targeted toward low-income groups. Our measure ranges from -1.0 (the poorest recipient receives all transfer income) to +1.0 (the richest recipient receives all transfer income).
[Table A3 in Excel Spreadsheet]
- 4) A measure of the extent of fiscal redistribution that is associated with several taxes and transfers (codes refer to LIS Household Income Components List; see Annex A below):
 - Sickness benefits (v16)
 - Occupational injury and disease benefits (v17)
 - Disability benefits (v18)
 - State old-age and survivors benefits (v19)
 - Child/family benefits (v20)
 - Unemployment compensation benefits (v21)
 - Maternity and other family leave benefits (v22)
 - Military/veterans/war benefits (v23)
 - Other social insurance benefits (v24)
 - Social assistance cash benefits (v25)
 - Near-cash benefits (v26)
 - Mandatory payroll taxes (v7+v13)
 - Income taxes (v11)
 [Table A4 in Excel Spreadsheet]

In measuring income, we have employed an equivalency scale that divides household size by the square root of the number of household members, weighting households by the number of members they include. As to missing data, we have included households which report zero primary income (i.e., all of their income is derived from the state) but have excluded households that report zero disposable income. We have employed standard LIS top- and bottom-coding conventions, top-coding income at 10 times the median of non-equivalized income and bottom-coding income at 1 percent of equivalized mean income.

A description of the decomposition method of Gini coefficient is given in sections 3.2 and 3.3.
